Abstract—Orthogonal time frequency space (OTFS) modulation is widely acknowledged as a prospective waveform for future wireless communication networks. To provide insights for the practical system design, this paper analyzes the outage probability of OTFS modulation with finite blocklength. To begin with, we present the system model and formulate the analysis of outage probability for OTFS with finite blocklength as an equivalent problem of calculating the outage probability with finite blocklength over parallel additive white Gaussian noise (AWGN) channels. Subsequently, we apply the equivalent noise approach to derive a lower bound on the outage probability of OTFS with finite blocklength under both average power allocation and water-filling power allocation strategies, respectively. Finally, the lower bounds of the outage probability are determined using the Monte-Carlo method for the two power allocation strategies. The impact of the number of resolvable paths and coding rates on the outage probability is analyzed, and the simulation results are compared with the theoretical lower bounds.

Index Terms—OTFS modulation, outage probability, finite blocklength, lower bound.

I. INTRODUCTION

The 6th-generation (6G) wireless communication networks are envisioned to provide ubiquitous connectivity for a diverse range of intelligent and highly mobile terminals, including autonomous vehicles, high-speed railways (HSRs), unmanned aerial vehicles (UAVs), and low-earth orbit (LEO) satellites [1]. Ensuring reliable and consistent performance in such high-mobility scenarios poses significant technical challenges for 6G networks. However, high-mobility broadband signal transmission over wireless channels suffers from significant difficulties due to the doubly selective property of the channel, including frequency selectivity and time selectivity. Mitigating time-selective fading caused by Doppler spread, which exceeds the channel's coherence time, is essential for ensuring robust and efficient communication in high-mobility scenarios. Consequently, research has focused on developing novel modulation waveforms and architectures to support communication in high-mobility scenarios of 6G networks.

Orthogonal frequency division multiplexing (OFDM) modulation has been widely adopted in 5th-generation (5G) cellular networks and WiFi networks. However, OFDM exhibits significant limitations in high-mobility scenarios, as large Doppler shifts disrupt the orthogonality of subcarriers and introduce severe inter-carrier interference (ICI). Recently, a novel two-dimensional modulation scheme, termed orthogonal time fre-

quency space (OTFS), has been proposed as a prospective solution for high-mobility communication scenarios [2]. Unlike traditional OFDM, which modulates information symbols in the time-frequency (TF) domain, OTFS maps the symbols onto the delay-Doppler (DD) domain. This transformation enables OTFS to effectively convert doubly selective TF domain channels into quasistatic channels in the DD domain. As a result, OTFS exhibits enhanced robustness against fading variations caused by high-mobility and provides improved performance in high-mobility scenarios with severe Doppler shifts [3].

The previously mentioned emerging technologies, such as autonomous vehicles, UAVs and LEO satellites, require not only seamless and reliable communication but also the ability to support services with varying quality of service (QoS) requirements. In such circumstances, guaranteeing reliable communication under fluctuating channel conditions and fulfilling diversity QoS requirements poses a crucial challenge, which is typically evaluated by means of outage probability. Several studies have explored outage probability analysis for OTFS systems and provided valuable insights into OTFS performance.

Chong et al. [4] analyze the outage performance of OTFS in both single-user and multi-user cases, deriving the lower bound of outage probability as a function of the achievable rates. In reference [5], the outage probability of a multi-UAV-aided LEO satellite communication system employing the OTFS scheme is analyzed, under the UAVs' user independent motion model. Closed-form expressions of the outage probability in OTFS cooperative communication systems, employing both decode-and-forward (DF) and amplify-and-forward (AF) protocols, are presented in [6]. Nevertheless, existing research on the outage performance of OTFS typically operates under the ideal assumption of infinitely long blocklength, which does not reflect the physical constraints of finite blocklength in real-world communication systems. Consequently, it is essential to investigate the outage probability of OTFS with finite blocklength to better align theoretical analysis with practical implementation.

Finite blocklength codes have been extensively studied as a foundation for short-packet communications, providing a critical approach to enabling low-latency services in communication systems. In the landmark work [7], Polyanskiy et al. derive a closed-form expression for the decoding error probability under finite blocklength transmission over additive

white Gaussian noise (AWGN) channels. Their results reveal that the decoding error probability for finite blocklength codes remains nonzero, even if the coding rate is below the Shannon capacity, and increases as the blocklength decreases. Recently, analytical studies on finite blocklength performance have been extended to various scenarios, including cooperative communication systems [8], non-orthogonal multiple access (NOMA) schemes [9] and green communications [10]. Furthermore, investigating the outage probability performance with finite blocklength provides a theoretical foundation for optimizing communication system latency and efficiency through blocklength allocation, power control and transmission rate selection [11].

In light of the preceding discussion, we are motivated to investigate the outage probability of OTFS with finite blocklength. The main contributions of this paper are summarized as follows: (1) Modeling and analyzing the outage probability of OTFS with finite blocklength, providing the first investigation that accounts for blocklength constraints in practical OTFS communication systems; (2) Deriving a lower bound on the outage probability of OTFS with finite blocklength through average power allocation by applying the equivalent noise approach; (3) Incorporating the water-filling power allocation strategy into the analysis to obtain the lower bound of the outage probability under optimal power allocation across multiple parallel fading paths.

II. SYSTEM MODEL

A. Delay-Doppler Channels of OTFS

The complex baseband channel impulse response $h(\tau, \nu)$ represents the DD domain channel's reaction to an impulse with a time delay τ and a Doppler shift ν . Let $w(t)$ denote the AWGN process, characterized by a one-sided power spectral density (PSD) of N_0 . Therefore, the signal $r(t)$, which is received at the receiver side with an input signal $s(t)$ over the DD domain channel, is expressed as follows:

$$r(t) = \iint h(\tau, \nu) s(t - \tau) e^{j2\pi\nu(t-\tau)} d\nu d\tau + w(t). \quad (1)$$

In high user-terminal mobility scenarios, modelling the DD domain channel requires far fewer parameters than modelling the channel in the TF domain. The reason can be attributed to the few number of reflectors, each associated with specific Doppler shifts and delays, within the transmission environment. The sparsity and separability of the DD domain channel allow the channel response $h(\tau, \nu)$ to be expressed as:

$$h(\tau, \nu) = \sum_{i=1}^L h_i \delta(\tau - \tau_i) \delta(\nu - \nu_i). \quad (2)$$

In (2), L denotes the number of independent resolvable paths, $\delta(\cdot)$ represents the Dirac delta function, and h_i , τ_i , and ν_i refer to the complex fading coefficient, delay, and Doppler shift, respectively, associated with the i -th path.

Without loss of generality, let us consider an OTFS system with frame duration NT , where N is the number of time slot, T is the time elapsed in a slot. And each time slot has M

symbols. Specifically, the delay and Doppler shift indices are denoted by l_i and k_i , where

$$\tau_i = \frac{l_i T}{M}, \nu_i = \frac{k_i}{NT} + \kappa_i. \quad (3)$$

In most cases, the delay index l_i lies within the interval $[0, l_{max}]$, where l_{max} is generally less than or equal to L_{CP} . Here L_{CP} denotes the length of the cyclic prefix, which is appended to the beginning of the sequence before the signal transmission. Therefore, the maximum value of the channel delay is $\tau_{max} = \frac{l_{max} T}{M}$. Similarly, it is assumed that $k_i \in [-k_{max}, k_{max}]$, which implies that the maximum value of the Doppler shift is $\nu_{max} = \frac{k_{max}}{NT}$. In (3), $-\frac{1}{2} < \kappa_i \leq \frac{1}{2}$ represents the fractional Doppler, which denotes the fractional offset relative to the nearest Doppler tap. It is unnecessary to consider fractional delays, as the time axis resolution of T/M is adequate to approximate the path delays to the nearest sampling points in typical wideband systems [12].

Let us turn our attention to the time-varying channel fading coefficient. For ease of expression, the channel fading coefficient vector is denoted as $\mathbf{h} = [h_1, h_2, \dots, h_L]$, with a size of $1 \times L$. The elements in $\mathbf{h}$ are $h_i = a_i + jb_i$, where a_i and b_i are independent and identically distributed (i.i.d.) Gaussian random variables with mean μ and variance $1/(2L)$. Especially when $\mu = 0$, $|h_i|$ follows the Rayleigh distribution. Each channel fading coefficient corresponds to a delay and a Doppler shift, the latter of which is assumed to follow the classic Jakes spectrum with respect to k_{max} . The channel coefficient, the delay and the Doppler spreads are mutually independent, and will be employed to construct channel models for simulations in the subsequent section.

B. Outage Probability with Finite Blocklength

Let $\mathbf{y}$ and $\mathbf{x}$ represent the DD domain transmitted and received symbol vectors, respectively. We now focus on the vector form representation of the input-output relationship in the DD domain,

$$\mathbf{y} = \mathbf{H}_{DD} \mathbf{x} + \mathbf{w}, \quad (4)$$

where, $\mathbf{H}_{DD}$ is the effective DD domain channel matrix

$$\mathbf{H}_{DD} = \sum_{i=1}^L h_i (\mathbf{F}_N \otimes \mathbf{I}_M) \mathbf{\Pi}^{l_i} \mathbf{\Delta}^{k_i + \kappa_i} (\mathbf{F}_N^H \otimes \mathbf{I}_M), \quad (5)$$

with $\mathbf{F}_N$ being the discrete Fourier transform matrices of size $N \times N$, $\mathbf{\Pi}$ being a forward cyclic shift permutation matrix describing the delay effect, and $\mathbf{\Delta} = \text{diag}\{\alpha^0, \alpha^1, \dots, \alpha^{MN-1}\}$ being a diagonal matrix describing the Doppler effect with $\alpha = e^{j\frac{2\pi}{MN}}$ [13]. $\mathbf{w}$ in equation (4) represents the equivalent sample vector of AWGN in DD domain with one-sided PSD of N_0 . In [14, Section 4.4], the OTFS input-output relationship in the time domain and the DD domain are derived, which proves that the noise in the DD domain remains AWGN.

Given the blocklength and error probability, reference [7] investigates the maximal achievable coding rate for Gaussian channels. With blocklength n and block error probability ϵ , the finite blocklength coding rate is expressed by:

$$R(n) = C - \sqrt{\frac{V}{n}} Q^{-1}(\epsilon) + \mathcal{O}\left(\frac{\log n}{n}\right), \quad (6)$$

where $Q^{-1}(\cdot)$ is the inverse Q-function, and the Q-function is typically defined as

$$Q(x) = \int_x^\infty \frac{1}{\sqrt{2\pi}} e^{-t^2/2} dt. \quad (7)$$

C is the channel capacity and V is the channel dispersion. Specifically, for the one-dimensional AWGN channel, we have

$$C = \frac{1}{2} \log_2(1 + \gamma), \quad (8)$$

$$V = \frac{\gamma(2 + \gamma)(\log e)^2}{2(1 + \gamma)^2}, \quad (9)$$

where, γ denotes signal-to-noise ratio (SNR).

In this paper, once a block error occurs, it is treated as an outage event, i.e., block error rate equals outage probability. Therefore, the outage probability with the finite blocklength can be calculated as:

$$P_{out} = Q \left[\sqrt{\frac{n}{V}} (C - R(n)) \right]. \quad (10)$$

In particular, it should be noted that a strict approximation of the maximal achievable coding rate can already be achieved when blocklengths are greater than 100 [7], and therefore the term $\mathcal{O}((\log n)/n)$ in (6) is neglected in this paper.

III. OUTAGE PERFORMANCE ANALYSIS

The OTFS with finite channel coding system model is presented in Fig. 1. The original binary sequence of length k is encoded at a rate R_c to produce a codeword of length n . Therefore, the channel coding rate can be represented as $R_c = k/n$. Then, the codeword are mapped into one OTFS DD domain frame. After applying inverse symplectic finite Fourier transform (ISFFT) and the Heisenberg transform, the frame is transmitted through the channel. The channel consists of L independent resolvable parallel AWGN paths. At the receiver, the signal $r(t)$ is converted back into the DD domain through the application of the Wigner transform followed by the symplectic finite Fourier transform (SFFT). The OTFS frame is subsequently reconstructed as a sequence of length k with an outage probability P_{out} through demapping and channel decoding. Therefore, on the basis of the normalized achievable capacity of OTFS [4], the outage probability of OTFS with finite blocklength is defined as

$$P_{out}^{theo} \triangleq \Pr \left\{ \log_2 \det \left(\mathbf{I}_{MN} + \frac{E_s}{N_0} \mathbf{H}_{DD}^H \mathbf{H}_{DD} \right) < k \right\}. \quad (11)$$

Fig. 2 illustrates the process of power allocation and SNR calculation for L -parallel AWGN paths in OTFS under finite blocklength conditions. Each path is characterized by its channel coefficient h_i . The transmit power allocated to the i -th path is denoted as W_i , and $W = \sum_{i=1}^L W_i$ denotes the total transmit power available for allocation to all L -parallel paths. σ_0^2 represents the noise power at the receiver. The remaining equations shown in Fig. 2 will be explained in the following paragraphs.

Reference [15] extends equation (6) to the one-dimensional L -parallel AWGN channel. The two-dimensional L -parallel

Fig. 1. The system model of OTFS with finite channel coding length.

AWGN channels can be equivalently represented as a superposition of one-dimensional $2L$ -parallel AWGN channels. Therefore, we can deduce the outage probability for OTFS with finite blocklength in two-dimensional L -parallel AWGN channels

$$P_{out} = Q \left[\sqrt{\frac{n}{V_L(\alpha)}} (C_L(\alpha) - R_c) \right], \quad (12)$$

where

$$C_L(\alpha) = \frac{1}{2} \sum_{i=1}^{2L} \log_2(1 + \alpha_i), \quad (13)$$

$$V_L(\alpha) = \frac{(\log e)^2}{2} \sum_{i=1}^{2L} \frac{\alpha_i(2 + \alpha_i)}{(1 + \alpha_i)^2}. \quad (14)$$

Furthermore, α_i represents the SNR of the i -th path, which is defined as $\alpha_i = \frac{W_i |h_i|^2}{\sigma_0^2}$.

Therefore, the problem of calculating the outage probability of OTFS with finite blocklength is reformulated as determining the outage probability for finite blocklength transmission over parallel AWGN channels. This reformulation assumes that all paths arrive at the receiver simultaneously, disregarding the adverse impact of different path delays on outage performance. Consequently, the derivation presented below represents the lower bound on the outage probability.

Consider calculating the outage probability for OTFS with finite blocklength employing both the average power allocation and the water-filling power allocation. For the average power allocation, it is simple to deduce that the SNR of the i -th path is $\alpha_i^{avg} = \frac{W |h_i|^2}{L \sigma_0^2}$. By combining (12) and α_i^{avg} , the outage probability of OTFS with finite blocklength can be derived using the average power allocation.

For the water-filling power allocation, the equivalent noise will be calculated for each path. To maximize the overall SNR across all paths, allocate higher power to paths with lower equivalent noise levels, and conversely, allocate lower power to paths with higher noise levels. Given that the noise power at the receiver is identical for all paths, the equivalent noise is inversely proportional to the received signal power. Therefore, the equivalent noise for each path can be expressed as

$$\varepsilon_i = \frac{\sigma_0^2}{|h_i|^2}. \quad (15)$$

The power allocation to each path can be determined based on the corresponding equivalent noise ε_i . The power P_i for each

Fig. 2. Power allocation and SNR calculation for L -parallel AWGN paths in OTFS with finite blocklength.

path is obtained using the conventional water-filling power allocation strategy, expressed as:

$$P_i = [\lambda - \varepsilon_i]^+, \quad (16)$$

where λ represents the water-filling level, which is the solution of the power constraint equation

$$\sum_{i=1}^L P_i = W. \quad (17)$$

Furthermore, the outage probability for OTFS with finite blocklength can be derived using the water-filling power allocation strategy, as given by

$$P_{out}^{wat} = Q \left[\sqrt{\frac{n}{V_L(\alpha)}} (C_L(\alpha) - R_c) \right], \quad (18)$$

where $C_L(\alpha)$ and $V_L(\alpha)$ are defined in (13) and (14), respectively, and $\alpha_i^{wat} = \frac{P_i |h_i|^2}{\sigma_0^2}$.

IV. PERFORMANCE EVALUATION

In this section, the Monte-Carlo method [16, Section 2.3] is employed to obtain the theoretical outage probability of OTFS with finite blocklength, as well as the outage probability lower bounds under average power allocation and water-filling power allocation. A comparative analysis is conducted between the theoretical results and the derived lower bounds. To maintain generality, we set $M = 32$, $N = 16$, $\Delta f = 7.5\text{KHz}$, $f_c = 4\text{GHz}$. As discussed in Section II-A, the channel coefficients are randomly generated following a complex Gaussian distribution with a mean of $\mu = 0$ and a variance of $1/(2L)$. The maximum delay index is set to 8, and the maximum Doppler index is set to 4, corresponding to a maximum velocity of 500 km/h.

We first compare the lower bound of outage probability under average power allocation and water-filling power allocation for different numbers of resolvable paths, as illustrated

Fig. 3. Outage probability lower bounds for different number of resolvable paths under average and water-filling power allocation, where $R_c = 0.8$.

in Fig. 3. For a given number of resolvable paths, it is evident that the optimal power allocation achieved by the water-filling allocation results in a lower outage probability compared to average power allocation. Furthermore, it is observed that in the low E_s/N_0 region, a higher number of resolvable paths exhibit higher outage probability than those with fewer paths. However, in the high E_s/N_0 region, the trend reverses, more resolvable paths achieving lower outage probability. This phenomenon can be attributed to the fact that as the number of resolvable paths increases, the energy allocated to each individual path is relatively reduced, especially for average power allocation. Moreover, a larger number of paths introduces additional interference. However, in the high E_s/N_0 region, the diversity gain progressively becomes dominant, reducing the outage probability in cases with more paths.

Fig. 4 illustrates the lower-bound curves of outage probability for average power allocation and water-filling power allocation at different coding rates with $L = 5$. It is obvious that lower coding rates result in smaller outage probability for the same E_s/N_0 . It is also worth noting that in the high E_s/N_0 region, the slopes of the curves are essentially identical.

Fig. 5 and Fig. 6 compare the theoretical results with the lower bound of outage probability under average power allocation for a coding rate of 0.8, with $L = 3$ and $L = 5$, respectively. Across the entire E_s/N_0 range, the outage probability lower bounds closely aligns with the theoretical results and exhibit a similar slope. An increased number of independent resolvable paths reduces the gap between the theoretical results and the lower bounds. It is evident that lower coding rates lead to improved outage probability performance.

V. CONCLUSIONS

In this paper, we have conducted an analysis of the outage probability of OTFS modulation with finite blocklength. We start from the system model of OTFS with finite channel coding rate. Then, we derived theoretical lower bounds on the outage probability under both average and water-filling

Fig. 4. Outage probability lower bounds for different coding rate under average and water-filling power allocation, where $P = 5$.

Fig. 5. Comparison of simulation and lower bound of outage probability with average power allocation, where $L = 3$.

Fig. 6. Comparison of simulation and lower bound of outage probability with average power allocation, where $L = 5$.

power allocation strategies, by formulating the problem as an equivalent analysis of finite blocklength over parallel AWGN channels. The performance evaluated through Monte-Carlo method reveal the impact of resolvable paths and coding rates on outage probability. Afterwards, the theoretical results are compared with the derived lower bounds. Our analysis provides insights into the design and optimization of OTFS systems, specifically focusing on blocklength allocation, power control and transmission rate selection, to improve performance in high-mobility communication scenarios.
