Abstract. RC4 is the stream cipher proposed by Rivest in 1987, which is widely used in a number of commercial products because of its simplicity and substantial security. RC4 exploits shuffle-exchange paradigm, which uses a permutation S . Many attacks have been reported so far. No study, however, has focused on correlations in the Pseudo-Random Generation (PRGA) between two permutations S and S' with some differences, nevertheless such correlations are related to an inherent weakness of shuffle-exchange-type PRGA. In this paper, we investigate the correlations between S and S' with some differences in the initial round. We show that correlations between S and S' remain before “ i ” is in the position where the nonzero-bit difference exists in the initial round, and that the correlations remain with non negligible probability even after “ i ” passed by the position. This means that the same correlations between S and S' will be observed after the 255-th round. This reveals an inherent weakness of shuffle-exchange-type PRGA.

1 Introduction

RC4 is the stream cipher proposed by Rivest in 1987, which is widely used in a number of commercial products because of its simplicity and substantial security. Though many cryptanalysis of RC4 have been proposed so far [1, 4, 13, 7, 2, 12, 8, 11, 9, 3, 5], it has remained secure under proper use. As a result, RC4 is widely used in many applications such as Secure Sockets Layer (SSL), Wired Equivalent Privacy (WEP), etc.

RC4 exploits shuffle-exchange paradigm, which uses a permutation $S = (S[0], \dots, S[N - 1])$ given in the initial, and outputs 8-bit data in each round by updating the permutation S , where typically each $S[i]$ ($i \in [0, N - 1]$) is 8 bits and $N = 256$. In more detail, RC4 consists of two algorithms, the Key Scheduling Algorithm (KSA) and the Pseudo Random Generation Algorithm (PRGA). KSA is given a secret key with ℓ bytes (typically, $5 \leq \ell \leq 16$) and generates the initial permutation S_0 , which is an input of PRGA. PRGA is given the initial permutation S_0 , uses two indices i and j , (where i is a public counter but j is one element of secret state information), updates S and j , and outputs

$Z = S[S[i] + S[j]]$ as a key stream at the end of each round. There are mainly two approaches to the cryptanalysis of RC4, analysis of the weaknesses of the KSA, and analysis of the weaknesses of the PRGA. Many works, however, focus on the bias between a secret key and the initial permutation, which is an input of PRGA. Some analysis of the weaknesses of the PRGA also focus on the correlation between the first keystream output of PRGA and the secret key. We have not seen any research on correlations in PRGA between two permutations with some differences. However, such correlations should be investigated, since it is reported that sets of two keys which output either the same initial permutations or initial permutations with differences of just a few bits can be intentionally induced [6]. Furthermore, correlations between outputs of two consecutive rounds is an inherent weakness of shuffle-exchange-type PRGA.

In this paper, we focus on a shuffle-exchange structure of PRGA, where 1 swap is executed in each round. We investigate how the structure mixes the permutation S , by observing correlations between two permutations, S and S' , with some differences in the initial round. The set of indices where differences exist in the initial round is represented by Diff_0 . The correlations are measured over (a) the difference value of two permutations $\Delta S = S \oplus S'$, (b) the difference value of two outputs of PRGA, $\Delta Z = Z \oplus Z'$, and (c) the difference value of two indices $\Delta j = j \oplus j'$. We start with $\text{Diff}_0 = \{\text{df}_0[1], \text{df}_0[2]\}$. Our results, however, are easily applicable to other cases where there exist differences Diff_0 with $\#\text{Diff}_0 > 2$ in the initial round.

We show theoretically that correlations between two permutations S and S' , such as $\Delta Z = 0$, $\Delta j = 0$, and the hamming weight of ΔS , remain when $i < \text{df}_0[1]$. Furthermore, we show that such correlations between two permutations S and S' remain with non negligible probability when $i \geq \text{df}_0[1]$, thus, the same correlations between permutations will be observed when $i < \text{df}_0[2]$. For example, the probability that such correlations remain when $i > \text{df}_0[1]$ is greater than 30% in the cases of $\text{df}_0[1] \geq 93$. We give the theoretical formulae of the probability of both outputs being equal when $i = \text{df}_0[1]$. All theoretical results have been confirmed experimentally.

This paper is organized as follows. Section 2 summarizes the known facts on RC4 together with notation. Section 3 investigates correlations in each round between two permutations S and S' with some differences in the initial round. Section 4 investigates correlations in each round between outputs of two permutations S and S' . Section 5 shows the experimental results which confirm all theories in Sections 3 and 4. Section 6 investigates how to predict inner states.

2 Preliminary

This section presents the KSA and the PRGA of RC4, after explaining the notations used in this paper.

S, S' : permutations

S_0, S'_0 : the initial permutations of PRGA

Diff_0 : the set of indices where differences between S and S' exist in the initial round

r : number of rounds ($r = 0$ means the initial round)

$df_0[1], df_0[2], \dots$: the positions where differences exist in the initial round
 $i_r, j_r (j'_r)$: i and j (j') of S (S') after r rounds
 $S_r (S'_r)$: the permutation S (S') after r rounds
 $S_r[i] (S'_r[i])$: the value of S_r (S'_r) in the position i after r rounds
 $\Delta S_r : S_r \oplus S'_r$
 $\Delta S_r[i] : S_r[i] \oplus S'_r[i]$
 $|\Delta S_r|$: the number of indices with $\Delta S_r[i] \neq 0$
 $Z_r (Z'_r)$: the output under S (S') at the r -th round
 $\Delta Z_r : Z_r \oplus Z'_r$
 $\Delta j_r : j_r \oplus j'_r$
 $\Delta State[0], \Delta State[1], \dots$: the state differences between S and S' (j and j') in a round r .
 (The state differences of i are omitted since the same i is used each other.)

RC4 has a secret internal state which is a permutation of all the $N = 2^n$ possible n -bit words and index j . RC4 generates a pseudo-random stream of bits (a keystream) which, for encryption, is combined with the plaintext using XOR; decryption is performed in the same way. To generate the keystream, the cipher makes use of a secret internal state which consists of two parts (shown in Figure 1): A key scheduling algorithm, KSA, which turns a random key (whose typical size is 40-256 bits) into an initial permutation S_0 of $\{0, \dots, N - 1\}$, and an output generation algorithm, PRGA, which uses the initial permutation to generate a pseudo-random output sequence.

The algorithm KSA consists of N loops. It initializes S to be the identity permutation, and both i and j to 0, and then repeats three simple operations: increment i , which acts as a counter, set j by using S and a secret key K with ℓ bytes where each word contains n bits, and swap two values of S in positions i and j . Finally, it outputs a random permutation $S = S_0$.

The algorithm PRGA is similar to KSA. It repeats four simple operations: increment i , which act as a counter, set j by using S and the previous j , swap two values of S in positions i and j , and output the value of S in position $S[i] + S[j]$. Each value of S is swapped at least once (possibly with itself) within any N consecutive rounds. All additions used in both KSA and PRGA are in general additions modulo N unless specified otherwise.

3 State Analysis of Permutations with Some Differences

This section analyzes correlations between two permutations, S and S' , with some differences in the initial round. The set of indices where differences exist in the initial round is represented by $\text{Diff}_0 = \{\text{df}_0[1], \text{df}_0[2], \dots\}$. The indices with nonzero bit differences are arranged in order of positions that i will reach after the next round. Therefore, if nonzero bit differences exist in positions 0 and $N - 1$ in the initial round, then $\text{Diff}_0 = \{\text{df}_0[1], \text{df}_0[2]\} = \{N - 1, 0\}$ since i will be incremented to 1 in the first round.

3.1 Overview of Analysis

Assume that two permutations S and S' with $\text{Diff}_0 = \{\text{df}_0[1], \text{df}_0[2]\}$ in the initial round are given, where $(S_0[\text{df}_0[1]], S_0[\text{df}_0[2]]) = (a, b)$ and $(S'_0[\text{df}_0[1]], S'_0[\text{df}_0[2]]) = (b, a)$ (See Figure 2). Then, the initial state of differences between S_0 and S'_0 is:

$$\Delta\text{State}[0] : (\Delta S[x] \neq 0 \iff x \in \text{Diff}_0) \wedge (\Delta j = 0).$$

Then, we analyze the conditions in each round in which the initial state changes from the current state to another, or remains the same.

Fig. 2. $\Delta\text{State}[0]$

Fig. 3. Event[1]

Fig. 4. Event[2]

Fig. 5. Event[3]

The transitions of state are different according to the position of i , that is, $i < \text{df}_0[1]$; $i = \text{df}_0[1]$ and the nonzero bit difference still exists in the position $\text{df}_0[1]$; $i = \text{df}_0[1]$ but the nonzero bit difference does not exist in the position $\text{df}_0[1]$, which are formalized as follows.

Event[1] : $i_r < \text{df}_0[1]$ (Figure 3),

Event[2] : $[i_r = \text{df}_0[1]] \wedge [\Delta S_{r-1}[\text{df}_0[1]] \neq 0]$ (Figure 4),

Event[3] : $[i_r = \text{df}_0[1]] \wedge [\Delta S_{r-1}[\text{df}_0[1]] = 0]$ (Figure 5).

Figures 3, 4, and 5 show each event, where $(x, x') = (b, a)$ or $x = x'$. We will see the reason for this in the following subsections. The following subsections describe each transition and the probability of its occurrence in each event. We will see that the state of differences between two permutations S and S' has the Markov property, that is, given the state in a certain round (the present state), the state in a future round (future states) is independent of past rounds.

3.2 Transitions of $\Delta\text{State}[0]$ before the nonzero bit difference

This subsection shows Theorem 1, which describes the transitions from the initial state in $\text{Event}[1]$ and their associated probabilities. The state diagram is given in Figure 6 .

Fig. 6. State Diagram of PRGA in $\text{Event}[1]$

Theorem 1. Assume that two initial permutations S and S' are in the state of differences $\Delta\text{State}[0]$ in the $(r-1)$ -th round, and that $\text{Event}[1]$ occurs in the r -th round.

(1) The state changes to the state $\Delta\text{State}[0]$ (resp. $\Delta\text{State}[1]$, resp. $\Delta\text{State}[2]$) if $j_r \notin \text{Diff}_0$ (resp. $j_r = \text{df}_0[2]$, resp. $j_r = \text{df}_0[1]$), where

$$\begin{aligned} \Delta\text{State}[0] &: [\Delta S_r[x] \neq 0 \iff x \in \text{Diff}_0] \wedge [\Delta j_r = 0], \\ \Delta\text{State}[1] &: [\Delta S_r[x] \neq 0 \iff x \in \text{Diff}_1] \wedge [\Delta j_r = 0], \\ \Delta\text{State}[2] &: [\Delta S_r[x] \neq 0 \iff x \in \text{Diff}_2] \wedge [\Delta j_r = 0]. \end{aligned}$$

and where $\text{Diff}_1 = \{\text{df}_1[1], \text{df}_1[2]\} = \{\text{df}_0[1], i_r\}$ and $\text{Diff}_2 = \{\text{df}_2[1], \text{df}_2[2]\} = \{\text{df}_0[2], i_r\}$.

(2) Each transition occurs with the following probabilities if j is distributed randomly:

$$\text{Prob}[\Delta\text{State}[0]] = \frac{N-2}{N}, \quad \text{Prob}[\Delta\text{State}[1]] = \frac{1}{N}, \quad \text{and} \quad \text{Prob}[\Delta\text{State}[2]] = \frac{1}{N},$$

where each probability is taken over choices of S and S' in state $\Delta\text{State}[0]$ in the initial round.

proof: (1) It is clear that $j_r = j'_r$ holds in any case, since $j_r = j_{r-1} + S_{r-1}[i_r]$, $\Delta j_{r-1} = 0$, and $i_r \notin \text{Diff}_0$. In the case of $j_r \notin \text{Diff}_0$, $\Delta S_{r-1}[i_r] = \Delta S_{r-1}[j_r] = 0$ holds and, thus, positions of non-zero-bit differences remain the same as those in $(r-1)$ -round. Therefore, $\Delta\text{State}[0]$ occurs. In the case of $j_r = \text{df}_0[2]$,

$$\begin{aligned} (S_r[i_r], S_r[j_r]) &= (S_{r-1}[j_r], S_{r-1}[i_r]) = (b, S_{r-1}[i_r]); \\ (S'_r[i_r], S'_r[j'_r]) &= (S'_{r-1}[j'_r], S'_{r-1}[i_r]) = (a, S'_{r-1}[i_r]); \end{aligned}$$

and, thus, the non-zero-bit difference in the position $\text{df}_0[2]$ moves to the current i_r . Therefore, $\Delta\text{State}[1]$ occurs. In the case of $j_r = \text{df}_0[1]$,

$$\begin{aligned} (S_r[i_r], S_r[j_r]) &= (S_{r-1}[j_r], S_{r-1}[i_r]) = (a, S_{r-1}[i_r]); \\ (S'_r[i_r], S'_r[j_r]) &= (S'_{r-1}[j_r], S'_{r-1}[i_r]) = (b, S'_{r-1}[i_r]); \end{aligned}$$

and, thus, the non-zero-bit difference in the position $\text{df}_0[1]$ moves to the current i_r . Therefore, $\Delta\text{State}[2]$ occurs.

(2) The probability that each state will occur follows from the above discussion. \square

Theorem 1 implies that

- $|\Delta S_r| = 2$ and $\Delta j_r = 0$ hold as long as i_r is not equal to the position that a nonzero bit difference exits in the initial round.
- If $j_r = \text{df}_0[1]$ at least once in the r -th round during $i_r < \text{df}_0[1]$, then the nonzero bit difference in the position $\text{df}_0[1]$ moves to the current i_r . As a result, the nonzero-bit difference that was originally in the position $\text{df}_0[1]$ affects neither $|\Delta S|$ nor Δj until the $(r + N - 1)$ -th round. This is the case in which **Event[3]** occurs.

The following corollary describes the detailed cases in which i is not equal to any position that a nonzero bit difference exits before the N -th round.

Corollary 1 *Assume that two initial permutations S and S' in the state of differences $\Delta\text{State}[0]$ are given. Then, if either of the following events occurs, then i is not equal to any position that a nonzero bit difference exits; and both $|\Delta S_r| = 2$ and $\Delta j_r = 0$ hold until the N -th round.*

$$\begin{aligned} \text{Event[4]} : [j_{r_1} = \text{df}_0[1](1 \leq \exists i_{r_1} < \text{df}_0[1])] \quad \wedge [j_{r_2} = \text{df}_0[2](i_{r_1} < \exists i_{r_2} < \text{df}_0[2])] \\ \text{Event[5]} : [j_{r_3} = \text{df}_0[2](1 \leq \exists i_{r_3} < \text{df}_0[1] - 1)] \wedge [j_{r_4} = \text{df}_0[1](i_{r_3} < \exists i_{r_4} < \text{df}_0[1])] . \end{aligned}$$

Note that i_{r_3} is less than $\text{df}_0[1] - 1$ since $i_{r_3} < i_{r_4} < \text{df}_0[1]$.

proof: Assume that **Event[4]** has occurred in (j_{r_1}, j_{r_2}) , that is, first $j_{r_1} = \text{df}_0[1]$ for $1 \leq i_{r_1} < \text{df}_0[1]$ has occurred. This means that $\Delta\text{State}[2]$ has occurred in the index of i_{r_1} and, thus, $\Delta S_{r_1}[x] \neq 0 \iff x \in \text{Diff}_2$. Therefore, the nonzero-bit difference in the position $\text{df}_0[1]$ moves to the position i_{r_1} . Next, it is assumed that $j_{r_2} = \text{df}_0[2](i_{r_1} < i_{r_2} < \text{df}_0[2])$ has occurred. Then, $\Delta S_{r_2}[x] \neq 0 \iff x \in \{i_{r_1}, i_{r_2}\}$ by applying Theorem 1 to Diff_2 . Thus, i is not equal to any position that a nonzero bit difference exits until the N -th round.

Assume that **Event[5]** has occurred in (j_{r_3}, j_{r_4}) , that is, first $j_{r_3} = \text{df}_0[2]$ for $1 \leq i_{r_3} < \text{df}_0[1] - 1$ has occurred. This means that $\Delta\text{State}[1]$ has occurred in the index of i_{r_3} and, thus, $\Delta S_{r_3}[x] \neq 0 \iff x \in \text{Diff}_1$. Then, the index $\text{df}_0[2]$ no longer indicates a nonzero bit difference. Next, it is assumed that $j_{r_4} = \text{df}_0[1](i_{r_3} < i_{r_4} < \text{df}_0[1])$ has occurred. Then, $\Delta S_{r_4}[x] \neq 0 \iff x \in \{i_{r_3}, i_{r_4}\}$ by applying Theorem 1 to Diff_1 . Thus, i is not equal to any position that a nonzero bit difference exits until the N -th round. \square

The probability that **Event[3]** occurs, $\text{Prob}[\text{Event[3]}]$, is computed by the next theorems.

Theorem 2. Assume that two initial permutations S and S' in the state of differences $\Delta\text{State}[0]$ with $\text{df}_0[1] \geq 5$ are given. Then, $\text{Event}[3]$ will occur with the following probability if j is distributed randomly:

$$\text{Prob}[\text{Event}[3]] = 1 - \left(\frac{N-1}{N}\right)^{\text{df}_0[1]-1},$$

where the probability is taken over choices of S and S' with differences in Diff_0 in the initial round.

proof: $\text{Event}[2]$, the complement of $\text{Event}[3]$, occurs if and only if $j \neq \text{df}_0[1]$ during $i < \text{df}_0[1]$. Therefore, $\text{Prob}[\text{Event}[3]] = 1 - \left(\frac{N-1}{N}\right)^{\text{df}_0[1]-1}$ if j is distributed randomly. \square

In the case of $\text{df}_0[1] < 5$, we can describe $\text{Prob}[\text{Event}[3]]$ by the conditions of S_0 as follows:

Theorem 3. Assume that two initial permutations S and S' in the state of differences $\Delta\text{State}[0]$ with $\text{df}_0[1] \leq 5$ are given. Then, $\text{Event}[3]$ will occur in the following probability if $S_0[1]$, $S_0[2]$, and $S_0[3]$ are distributed randomly:

- (1) In the case of $\text{df}_0[1] = 2$, $\text{Prob}[\text{Event}[3]] = \text{Prob}[S_0[1] = j_1 = 2] = \frac{1}{N}$,
(2) In the case of $\text{df}_0[1] = 3$,

$$\text{Prob}[\text{Event}[3]] = \text{Prob}[S_0[1] = 3] + \text{Prob}[S_0[1] \neq 2, 3 \wedge S_0[1] + S_0[2] = 3] = \frac{2N-3}{N(N-1)},$$

- (3) In the case of $\text{df}_0[1] = 4$,

$$\begin{aligned} \text{Prob}[\text{Event}[3]] &= \text{Prob}[S_0[1] = 2] + \text{Prob}[S_0[1] = 4] + \text{Prob}[S_0[1] = 3 \wedge S_0[2] = N-2] \\ &\quad + \text{Prob}[S_0[1] \neq 2, 3, 4 \wedge S_0[3] \neq 0, 1 \wedge S_0[1] + S_0[2] + S_0[3] = 4] \\ &= \frac{2(2N-3)}{N(N-1)}, \end{aligned}$$

where the probability is taken over choices of S and S' with differences in Diff_0 in the initial round.

proof: (1) $\text{Event}[3]$ occurs if and only if $j_1 = \text{df}_0[1] = 2$, where $j_1 = j_0 + S_0[1] = S_0[1]$. Therefore, $\text{Prob}[\text{Event}[3]] = \text{Prob}[S_0[1] = 2] = \frac{1}{N}$.

(2) $\text{Event}[3]$ occurs if and only if $j_1 = \text{df}_0[1] = 3$ or $j_2 = \text{df}_0[1] = 3$. If $S_0[1] = 3$, then we get $j_1 = j_0 + S_0[1] = S_0[1] = 3 = \text{df}_0[1]$. If $S_0[1] \neq 2$, then $S_0[1] = j_1 \neq 2$, which means that $S_0[1]$ is not swapped with $S_0[2]$ in the first round. This implies that $S_1[2] = S_0[2]$. Thus, if $[S_0[1] \neq 2, 3] \wedge [S_0[1] + S_0[2] = 3]$, we get $j_2 = j_1 + S_1[2] = S_0[1] + S_0[2] = 3 = \text{df}_0[1]$. Therefore, $\text{Prob}[\text{Event}[3]] = \frac{1}{N} + \frac{N-2}{N(N-1)} = \frac{2N-3}{N(N-1)}$.

(3) $\text{Event}[3]$ occurs if and only if $j_1 = \text{df}_0[1] = 4$, $j_2 = \text{df}_0[1] = 4$, or $j_3 = \text{df}_0[1] = 4$. If $S_0[1] = 4$, then we get $j_1 = j_0 + S_0[1] = S_0[1] = 4 = \text{df}_0[1]$. If $S_0[1] = 2$, then $j_1 = j_0 + S_0[1] = 2$; $S_0[1]$ is swapped with $S_0[2]$; and, we get $j_2 = j_1 + S_1[2] = j_1 + S_0[1] = 4 = \text{df}_0[1]$. Note that $S_0[1]$ is swapped with $S_0[2]$ if and only if $S_0[1] = 2$. If $S_0[1] \neq 2, 4$ and $S_0[1] + S_0[2] = 4$, then we get $j_2 = j_1 + S_1[2] = S_0[1] + S_0[2] = 4 = \text{df}_0[1]$.

If $S_0[1] = 3$ and $S_0[2] = N-2$, then $j_1 = S_0[1] = 3$; and $S_0[1]$ is swapped with $S_0[3]$, which implies that $(S_1[1], S_1[3]) = (S_0[3], S_0[1])$. Then, in the 2nd round, $j_2 = j_1 + S_1[2] = 3 + S_0[2] = 1$; and $S_1[2]$ is swapped with $S_1[1]$, which implies that $S_2[3] = S_1[3] = 3$. Thus, in the 3rd round, we get $j_3 = j_2 + S_2[3] = 4$. Note that $S_0[1]$ is swapped with $S_0[3]$ if and only if $S_0[1] = 3$.

If $S_0[1] \neq 2, 3, 4$; $S_0[3] \neq 0, 1$; and $S_0[1] + S_0[2] + S_0[3] = 4$, then $S_1[2] = S_0[2]$; $S_1[3] = S_0[3]$; and $S_0[1] + S_0[2] \neq 3$. This implies that $S_1[3]$ is not swapped with $S_1[2]$ and that $S_2[3] = S_1[3]$. Thus, we get $j_3 = S_0[1] + S_0[2] + S_0[3] = 4$. To sum up all conditions, which are independent of each other, $\text{Prob}[\text{Event}[3]] = \frac{2}{N} + \frac{N-2}{N(N-1)} + \frac{1}{N(N-1)} + \frac{N-3}{N(N-1)} = \frac{2(2N-3)}{N(N-1)}$. \square

3.3 Transitions of $\Delta\text{State}[0]$ on the nonzero bit difference

This subsection shows Theorem 4, which describes each transition of the initial state $\Delta\text{State}[0]$ and the probability of its occurrence in $\text{Event}[2]$. The state diagram is given in Figure 7.

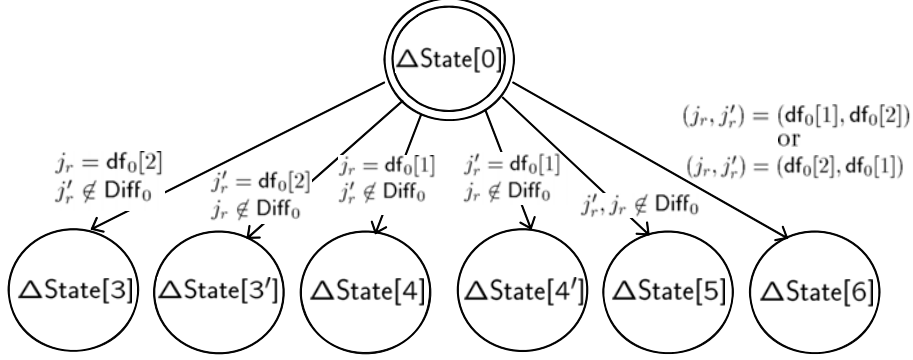

Fig. 7. State Diagram of PRGA in $\text{Event}[2]$

Theorem 4. Assume that two permutations S and S' are in the state of differences $\Delta\text{State}[0]$ in the $(r-1)$ -th round.

(1) The state changes to $\Delta\text{State}[3]$ (resp. $\Delta\text{State}[3']$, resp. $\Delta\text{State}[4]$, resp. $\Delta\text{State}[4']$, resp. $\Delta\text{State}[5]$, resp. $\Delta\text{State}[6]$), if $[j_r = \text{df}_0[2]] \wedge [j'_r \notin \text{Diff}_0]$ (resp. $[j'_r = \text{df}_0[2]] \wedge [j_r \notin \text{Diff}_0]$, resp. $[j_r = \text{df}_0[1]] \wedge [j'_r \notin \text{Diff}_0]$, resp. $[j'_r = \text{df}_0[1]] \wedge [j_r \notin \text{Diff}_0]$, resp. $[j'_r, j_r \notin \text{Diff}_0]$, resp. $[j'_r, j_r \in \text{Diff}_0]$), where

$$\begin{aligned} \Delta\text{State}[3] : & [\Delta S_r[x] \neq 0 \iff x \in \text{Diff}_3] \wedge [\Delta j_r \neq 0], \\ \Delta\text{State}[3'] : & [\Delta S_r[x] \neq 0 \iff x \in \text{Diff}_{3'}] \wedge [\Delta j_r \neq 0], \\ \Delta\text{State}[4] : & [\Delta S_r[x] \neq 0 \iff x \in \text{Diff}_4] \wedge [\Delta j_r \neq 0], \\ \Delta\text{State}[4'] : & [\Delta S_r[x] \neq 0 \iff x \in \text{Diff}_{4'}] \wedge [\Delta j_r \neq 0], \\ \Delta\text{State}[5] : & [\Delta S_r[x] \neq 0 \iff x \in \text{Diff}_5] \wedge [\Delta j_r \neq 0], \\ \Delta\text{State}[6] : & [|\Delta S_r| = 0] \wedge [\Delta j_r \neq 0], \end{aligned}$$

where

$$\begin{aligned}
\text{Diff}_3 &= \{\text{df}_3[1], \text{df}_3[2]\} &= \{\text{df}_0[1], j'_r\} &= \{i_r, j'_r\}, \\
\text{Diff}_{3'} &= \{\text{df}_{3'}[1], \text{df}_{3'}[2]\} &= \{\text{df}_0[1], j_r\} &= \{i_r, j_r\}, \\
\text{Diff}_4 &= \{\text{df}_4[1], \text{df}_4[2], \text{df}_4[3]\} &= \{\text{df}_0[1], \text{df}_0[2], j'_r\} &= \{i_r, \text{df}_0[2], j'_r\}, \\
\text{Diff}_{4'} &= \{\text{df}_{4'}[1], \text{df}_{4'}[2], \text{df}_{4'}[3]\} &= \{\text{df}_0[1], \text{df}_0[2], j_r\} &= \{i_r, \text{df}_0[2], j_r\}, \\
\text{Diff}_5 &= \{\text{df}_5[1], \text{df}_5[2], \text{df}_5[3], \text{df}_5[4]\} &= \{\text{df}_0[1], \text{df}_0[2], j_r, j'_r\} &= \{i_r, \text{df}_0[2], j_r, j'_r\}.
\end{aligned}$$

(2) Each transition occurs with the following probability, if j is distributed randomly:

$$\begin{aligned}
\text{Prob} [\Delta\text{State}[3] \vee \Delta\text{State}[3']] &= \text{Prob} [\text{Event}[2]] \cdot \frac{2(N-2)}{N(N-1)}, \\
\text{Prob} [\Delta\text{State}[4] \vee \Delta\text{State}[4']] &= \text{Prob} [\text{Event}[2]] \cdot \frac{2(N-2)}{N(N-1)}, \\
\text{Prob} [\Delta\text{State}[5]] &= \text{Prob} [\text{Event}[2]] \cdot \frac{(N-2)(N-3)}{N(N-1)}, \\
\text{Prob} [\Delta\text{State}[6]] &= \text{Prob} [\text{Event}[2]] \cdot \frac{2}{N(N-1)}.
\end{aligned}$$

proof: (1) It is clear that $j_r \neq j'_r$ in each case, since $\Delta j_r = \Delta j_{r-1} + \Delta S_{r-1}[i_r] = \Delta S_{r-1}[i_r] \neq 0$. In the case of $j_r = \text{df}_0[2]$ and $j'_r \notin \text{Diff}_0$, $S_{r-1}[i_r] = S_{r-1}[\text{df}_0[1]] = a$ is swapped with $S_{r-1}[j_r] = b$; $S'_{r-1}[i_r] = S'_{r-1}[\text{df}_0[1]] = b$ is swapped with $S'_{r-1}[j_r]$, which implies that $S'_{r-1}[\text{df}_0[2]] = a$ remains the same. Thus, we get $\Delta S_r[x] \neq 0 \iff x \in \text{Diff}_3$ after the r -th round. In the case of $j'_r = \text{df}_0[2]$ and $j_r \notin \text{Diff}_0$, the same also holds.

In the case of $j_r = \text{df}_0[1]$ and $j'_r \notin \text{Diff}_0$, $i_r = j_r = \text{df}_0[1]$ occurs; $S_{r-1}[i_r] = S_{r-1}[j_r] = a$ remains the same; and $S'_{r-1}[i_r] = b$ is swapped with $S'_{r-1}[j_r]$. Thus, we get $\Delta S_r[x] \neq 0 \iff x \in \text{Diff}_4$ after the r -th round. In the case of $j'_r = \text{df}_0[1]$ and $j_r \notin \text{Diff}_0$, the same also holds.

In the case of $j'_r, j_r \notin \text{Diff}_0$, $S_{r-1}[i_r] = a$ (resp. $S'_{r-1}[i_r] = b$) is swapped with $S_{r-1}[j_r]$ (resp. $S'_{r-1}[j'_r]$), where nonzero-bit difference did not exist; and both $S_{r-1}[\text{df}_0[2]] = b$ and $S'_{r-1}[\text{df}_0[2]] = a$ still remain the same. Thus, we get $\Delta S_r[x] \neq 0 \iff x \in \text{Diff}_5$ after the r -th round.

In the case of $(j_r, j'_r) = (\text{df}_0[1], \text{df}_0[2])$, $S'_{r-1}[i_r] = S'_{r-1}[\text{df}_0[1]] = b$ is swapped with $S'_{r-1}[j'_r] = S'_{r-1}[\text{df}_0[2]] = a$ while both $S_{r-1}[i_r] = S_{r-1}[j_r] = a$ and $S_{r-1}[j_r] = b$ remain the same. Thus, all nonzero-bit differences disappear after swapping in the r -th round. The same also holds in the case of $(j_r, j'_r) = (\text{df}_0[2], \text{df}_0[1])$.

(2) The probability that each state will occur follows from the above discussion. \square

4 Correlation between outputs and state transitions

This section analyzes the differences between outputs of two permutations S and S' in each transition described in Section 3, where two initial permutations S and S' are in the state of differences $\Delta\text{State}[0]$.

4.1 Outputs before the nonzero-bit difference

This subsection investigates the correlation between outputs of two permutations in each transition before the first nonzero-bit difference (i.e. $i < \text{df}_0[1]$). The states of differences of two permutations in any round $r < \text{df}_0[1]$ are $\Delta\text{State}[0]$, $\Delta\text{State}[1]$, or $\Delta\text{State}[2]$ from Theorem 1. The probability that both outputs of permutations are equal, $\text{Prob}[\Delta Z = 0]$, is given in the next theorem.

Proposition 1 *Assume that two initial permutations S and S' are in the state of differences $\Delta\text{State}[0]$ in the $(r - 1)$ -th round, and that $\text{Event}[1]$ occurs in the r -th round. Then, $\text{Prob}[\Delta Z = 0]$ in each state is as follows:*

$$\text{Prob}[\Delta Z = 0] = \frac{N-2}{N}, \frac{2}{N(N-1)}, \text{ or } \frac{2}{N(N-1)}$$

if $\Delta\text{State}[0]$, $\Delta\text{State}[1]$, or $\Delta\text{State}[2]$ occurs, respectively.

proof: Theorem 1 has shown that

- $\Delta j_r = 0$ and $j_r, i_r \notin \text{Diff}_0$ if $\Delta\text{State}[0]$,
- $\Delta j_r = 0$, $i_r \in \text{Diff}_1$ and $j_r \notin \text{Diff}_1$ if $\Delta\text{State}[1]$,
- $\Delta j_r = 0$, $i_r \in \text{Diff}_1$ and $j_r \notin \text{Diff}_2$ if $\Delta\text{State}[2]$.

Then, the necessary and sufficient conditions for $\Delta Z = 0$ in each state are as follows.

$$\begin{aligned} \text{In } \Delta\text{State}[0] : \Delta Z = 0 &\iff [\Delta(S_r[i_r] + S_r[j_r]) = 0] \wedge [S_r[i_r] + S_r[j_r] \notin \text{Diff}_0] \\ &\iff S_r[i_r] + S_r[j_r] \notin \text{Diff}_0 \end{aligned}$$

$$\text{Thus, } \text{Prob}[\Delta Z = 0] = \frac{N-2}{N}.$$

$$\begin{aligned} \text{In } \Delta\text{State}[1] : \Delta Z = 0 &\iff [\Delta(S_r[i_r] + S_r[j_r]) \neq 0] \wedge [S_r[i_r] + S_r[j_r], S'_r[i_r] + S'_r[j_r] \in \text{Diff}_1] \\ &\iff S_r[i_r] + S_r[j_r], S'_r[i_r] + S'_r[j_r] \in \text{Diff}_1 \end{aligned}$$

$$\text{Thus, } \text{Prob}[\Delta Z = 0] = \frac{2}{N(N-1)} \text{ since } \#\text{Diff}_1 = 2 \text{ and } S_r[i_r] + S_r[j_r] \neq S'_r[i_r] + S'_r[j_r].$$

$$\begin{aligned} \text{In } \Delta\text{State}[2] : \Delta Z = 0 &\iff [\Delta(S_r[i_r] + S_r[j_r]) \neq 0] \wedge [S_r[i_r] + S_r[j_r], S'_r[i_r] + S'_r[j_r] \in \text{Diff}_2] \\ &\iff S_r[i_r] + S_r[j_r], S'_r[i_r] + S'_r[j_r] \in \text{Diff}_2 \end{aligned}$$

$$\text{Thus, } \text{Prob}[\Delta Z = 0] = \frac{2}{N(N-1)} \text{ since } \#\text{Diff}_1 = 2 \text{ and } S_r[i_r] + S_r[j_r] \neq S'_r[i_r] + S'_r[j_r].$$

From the above, Proposition 1 follows. \square

From Theorem 1 and Proposition 1, the probability of $\text{Prob}[\Delta Z = 0]$ if $r < \text{df}_0[1]$ (i.e. $i < \text{df}_0[1]$) can be computed as follows.

Corollary 2 *Assume that two initial permutations S and S' with $\text{Diff}_0 = \{\text{df}_0[1], \text{df}_0[2]\}$ are given. Then, $\text{Prob}[\Delta Z = 0] = \left(\frac{N-2}{N}\right)^2 + \frac{4}{N^2(N-1)}$, if $r < \text{df}_0[1]$.*

4.2 Outputs on the nonzero-bit difference

This subsection investigates the correlation between outputs of two permutations in each transition when $r = \text{df}_0[1]$ (i.e. $i = \text{df}_0[1]$). The probability that both outputs are equal, $\text{Prob}[\Delta Z = 0]$, is given in the next theorem.

Proposition 2 Assume that two initial permutations S and S' are in the state of differences $\Delta\text{State}[0]$ in the $(r-1)$ -th round, and that $\text{Event}[2]$ occurs in the r -th round. Then, $\text{Prob}[\Delta Z = 0]$ in each state is as follows:

$$\begin{aligned} \text{Prob}[\Delta Z = 0] &= \frac{2}{N(N-1)} && \text{if } \Delta\text{State}[3] \vee \Delta\text{State}[3'] \\ \text{Prob}[\Delta Z = 0] &= \frac{N-3}{N(N-2)} + \frac{3}{N(N-1)} && \text{if } \Delta\text{State}[4] \vee \Delta\text{State}[4'] \\ \text{Prob}[\Delta Z = 0] &= \frac{N-4}{N(N-3)} + \frac{4}{N(N-1)} && \text{if } \Delta\text{State}[5] \\ \text{Prob}[\Delta Z = 0] &= 0 && \text{if } \Delta\text{State}[6] \end{aligned}$$

proof: Let c and $c' \in [0, N-1]$ be values in positions of j_r and j'_r before swapping in the r -th round, that is, $(c, c') = (S_{r-1}[j_r], S'_{r-1}[j'_r])$. On the other hand, $(a, b) = (S_{r-1}[\text{df}_0[1]], S_{r-1}[\text{df}_0[2]]) = (S'_{r-1}[\text{df}_0[2]], S'_{r-1}[\text{df}_0[1]])$. (See Figure 2). Theorem 4 has shown that:

$$\begin{aligned} \Delta\text{State}[3] : (S_r[i_r], S_r[j_r]) &= (b, a) \wedge (S'_r[i_r], S'_r[j'_r]) = (c', b) \text{ (i.e. } c = b \text{ and } c' \neq a, b); \\ \Delta\text{State}[4] : (S_r[i_r], S_r[j_r]) &= (a, a) \wedge (S'_r[i_r], S'_r[j'_r]) = (c', b) \text{ (i.e. } a = c \text{ and } c' \neq a, b); \\ \Delta\text{State}[5] : (S_r[i_r], S_r[j_r]) &= (c, a) \wedge (S'_r[i_r], S'_r[j'_r]) = (c', b) \text{ (i.e. } c' \neq c \text{ and } c', c \neq a, b); \\ \Delta\text{State}[6] : \Delta S_r = 0, (S_r[i_r], S_r[j_r]) &= (a, a) \wedge (S'_r[i_r], S'_r[j'_r]) = (a, b) \text{ (i.e. } i_r = j_r); \\ &\text{or } \Delta S_r = 0, (S_r[i_r], S_r[j_r]) = (b, a) \wedge (S'_r[i_r], S'_r[j'_r]) = (b, b) \text{ (i.e. } i_r = j'_r). \end{aligned}$$

Therefore, the necessary and sufficient conditions of $\Delta Z = 0$ in each state are as follows.

In $\Delta\text{State}[3] : \Delta Z = 0$

$$\begin{aligned} &\iff [S_r[i_r] + S_r[j_r], S'_r[i_r] + S'_r[j'_r] \in \text{Diff}_3] \wedge [\Delta(S_r[i_r] + S_r[j_r]) \neq 0] \\ &\iff [(a + b, c' + b) = (\text{df}_0[1], j'_r), (j'_r, \text{df}_0[1])]. \end{aligned}$$

Thus, $\text{Prob}[\Delta Z = 0] = \frac{2}{N(N-1)}$ since $a + b \neq c' + b$ always holds.

The same reasoning holds in the case of $\Delta\text{State}[3']$.

In $\Delta\text{State}[4] : \Delta Z = 0$

$$\begin{aligned} &\iff [(\Delta(S_r[i_r] + S_r[j_r]) = 0) \wedge [S_r[i_r] + S_r[j_r] \notin \text{Diff}_4] \vee [(\Delta(S_r[i_r] + S_r[j_r]) \neq 0) \wedge \\ &\quad [S_r[i_r] + S_r[j_r], S'_r[i_r] + S'_r[j'_r] \in \text{Diff}_4] \wedge S_r[S_r[i_r] + S_r[j_r]] = S'_r[S'_r[i_r] + S'_r[j'_r]]] \\ &\iff [2a = c' + b \wedge 2a \notin \text{Diff}_4] \vee [(2a, c' + b) = (i_r, \text{df}_0[2]), (j'_r, i_r), (\text{df}_0[2], i_r)]. \end{aligned}$$

Thus, $\text{Prob}[\Delta Z = 0] = \frac{N-3}{N(N-2)} + \frac{3}{N(N-1)}$.

The same reasoning holds in the case of $\Delta\text{State}[4']$.

In $\Delta\text{State}[5] : \Delta Z = 0$

$$\begin{aligned} &\iff [(\Delta(S_r[i_r] + S_r[j_r]) = 0) \wedge [S_r[i_r] + S_r[j_r] \notin \text{Diff}_5] \vee [(\Delta(S_r[i_r] + S_r[j_r]) \neq 0) \wedge \\ &\quad [S_r[i_r] + S_r[j_r], S'_r[i_r] + S'_r[j'_r] \in \text{Diff}_5] \wedge S_r[S_r[i_r] + S_r[j_r]] = S'_r[S'_r[i_r] + S'_r[j'_r]]] \\ &\iff [c + a = c' + b \wedge c + a \notin \text{Diff}_5] \vee \\ &\quad [(a + c, b + c') = (\text{df}_0[1], j_r), (j_r, \text{df}_0[2]), (\text{df}_0[2], j'_r), (j'_r, \text{df}_0[1])], \end{aligned}$$

Thus, $\text{Prob}[\Delta Z = 0] = \frac{N-4}{N(N-3)} + \frac{4}{N(N-1)}$.

In $\Delta\text{State}[6] : \text{Prob}[\Delta Z = 0]$ since $\Delta(S_r[i_r] + S_r[j_r]) \neq 0$ and $\Delta S_r = 0$.

From the above, the proposition follows. \square

The probability $\text{Prob}[\Delta Z = 0]$ when $i = \text{df}_0[1]$ follows immediately from Theorem 4 and Proposition 2.

Corollary 3 Assume that two permutations S and S' in the $(r-1)$ -th round are in $\Delta\text{State}[0]$ and $\text{Event}[2]$ occurs in the r -th round. Then, the probability that

both outputs are equal in the r -th round, $\text{Prob}[\Delta Z = 0]$, is given as follows:

$$\text{Prob}[\Delta Z = 0] = \text{Prob}[\text{Event}[2]] \cdot \left(\frac{N^2 - 4N + 2}{N^2(N-1)} + \frac{2(2N-1)(N-2)}{N^2(N-1)^2} \right)$$

From Corollaries 2 and 3, we get the following theorem.

Theorem 5. *Assume that two initial permutations S and S' with $\text{Diff}_0 = \{\text{df}_0[1], \text{df}_0[2]\}$ are given. Then, the probability $P_1 = \text{Prob}[\Delta Z = 0]$ in the round $r = \text{df}_0[1]$ is given as*

$$\begin{aligned} P_1 &= P_2 \cdot \left(\left(\frac{N-2}{N} \right)^2 + \frac{4}{N^2(N-1)} \right) + (1 - P_2) \cdot \left(\frac{N^2 - 4N + 2}{N^2(N-1)} + \frac{2(2N-1)(N-2)}{N^2(N-1)^2} \right), \\ &= P_2 \cdot \left(\left(\frac{N-2}{N} \right)^2 - \frac{N^2 - 4N - 2}{N^2(N-1)} - \frac{2(2N-1)(N-2)}{N^2(N-1)^2} \right) + \frac{N^2 - 4N + 2}{N^2(N-1)} + \frac{2(2N-1)(N-2)}{N^2(N-1)^2}, \end{aligned}$$

where $P_2 = \text{Prob}[\text{Event}[3]]$.

proof: The state of differences between two permutations has the Markov property. Therefore, the probability $\text{Prob}[\Delta Z = 0]$ in $r = \text{df}_0[1]$ is determined only by the state in the r -th round, where either **Event**[2] or **Event**[3] occurs. Theorem 5 follows from this fact. \square

The second term of $(1 - P_2) \cdot \left(\frac{N^2 - 4N + 2}{N^2(N-1)} + \frac{2(2N-1)(N-2)}{N^2(N-1)^2} \right)$ can be dealt with as an error term if $\text{df}_0[1]$ is large, which will be discussed in Section 5.

5 Experimental Results and New Bias

This section shows experimental results of Theorems 2, 3, and 5, and Corollary 2 in Sections 3 and 4. All experiments were conducted under the following conditions: execute KSA of RC4 with $N = 256$ for 10^8 randomly chosen keys of 16 bytes, generate the initial permutation S_0 , and set another initial permutation S'_0 with Diff_0 . Experiments are executed over the following sets of Diff_0 : $\text{df}_0[1] = 2, \dots, 255^1$ for Theorems 2 and 3; and $\text{Diff}_0 = \{\text{df}_0[1], \text{df}_0[2]\} = \{2 - 254, 255\}$, $\{2, 3 - 255\}$, and $\{3, 4 - 255\}$ for Theorem 5 and Corollary 2. The percentage absolute error ϵ of experimental results compared with theoretical results is computed by $\epsilon = \frac{|\text{experimental value} - \text{theoretical value}|}{\text{experimental value}} \times 100(\%)$, which is also used in [10].

5.1 Experimental Results of **Event**[3]

Figure 8 shows experimental results of $\text{Prob}[\text{Event}[3]]$ and its associated percentage absolute error, where the theoretical value is computed by Theorems 2 and 3. The horizontal axis represents $\text{df}_0[1] = 2, \dots, 255$. The left side of vertical axis represents $\text{Prob}[\text{Event}[3]]$, and the right side represents the percentage absolute error. Table 1 shows the cases of $\text{df}_0[1] \leq 6$ in detail.

Only the cases of $2 \leq \text{df}_0[1] \leq 6$ give the percentage absolute error $\epsilon \geq 5$, and, thus, our theoretical formulae closely match the experimental results if

¹ **Event**[3] does not depend on $\text{df}_0[2]$. See Theorems 2 and 3.

$df_0[1] > 6$. The initial permutation S_0 , that is the output of KSA, has a great influence on $\text{Event}[3]$ when $df_0[1]$ is small. Our results indicate that the bias in S_0 is propagated to $\text{Prob}[\text{Event}[3]]$ as the bias in S_0 has been reported in [8, 2, 10].

Figure 8 also indicates that the nonzero bit difference in the position $df_0[1]$ moves to another position until $i = df_0[1]$ with $\text{Prob}[\text{Event}[3]] > 30\%$ when $df_0[1] \geq 93$ and, thus, the correlations between S and S' such as $\Delta j = 0$ and $|\Delta S| = 2$ remain the same until $i = df_0[2]$.

5.2 Experimental Results of Outputs

Figure 9 shows experimental results of $\text{Prob}[\Delta Z = 0]$ in $r = df_0[1] - 1$, $df_0[1]$, and $df_0[1] + 1$, and percentage absolute error in $r = df_0[1]$ (i.e. $i = df_0[1] - 1$), where the theoretical value is computed by Theorem 5. The horizontal axis represents $df_0[1] = 2, \dots, 254$. The left side of vertical axis represents $\text{Prob}[\Delta Z = 0]$, and the right side represents the percentage absolute error. By using the experimental results, we investigate each case of outputs before or on the nonzero-bit difference.

Outputs before the nonzero-bit difference:

Let us discuss $\text{Prob}[\Delta Z = 0]$ in $r = df_0[1] - 1$ (i.e. $i = df_0[1] - 1$) for $df_0[1] = 2, \dots, 254$. The probability is theoretically estimated in Corollary 2. Our theoretical and experimental results indicate that both outputs of two permutations are coincident with a high probability $\text{Prob}[\Delta Z = 0] > 0.98$ during $i < df_0[1]^2$.

Let us discuss³ $\text{Prob}[\Delta Z = 0]$ in $r = df_0[1] + 1$ for $df_0[1] = 2, \dots, 253$, where $df_0[1] + 1 = i < df_0[2]$. Actually, it corresponds to the case in which i is before the nonzero bit difference $df_0[2]$ since $df_0[1] + 1$ is an index of nonzero bit difference when $i = df_0[1] + 1$ from the fact of $df_0[1] + 1 < df_0[2]$.

Our experimental results show that $\text{Prob}[\Delta Z = 0]$ in the round $df_0[1] + 1$ is almost the same as in the round $df_0[1]$, which reflects the results in Theorem 1. To sum up, we see that it is highly probable that both outputs of permutations are coincident as long as i does not indicate the index of nonzero bit difference in the current round.

Table 1. Experimental results with $\epsilon > 5$ of $\text{Event}[3]$

| $df_0[1]$ | Theoretical value | Experimental value | $\epsilon(\%)$ |
|-----------|-------------------|--------------------|----------------|
| 2 | 0.003906 | 0.005350 | 26.991 |
| 3 | 0.007797 | 0.009069 | 14.027 |
| 4 | 0.015548 | 0.018221 | 14.667 |
| 5 | 0.015534 | 0.016751 | 7.265 |
| 6 | 0.019379 | 0.020501 | 5.472 |

² Similar experimental results to $i = df_0[1] - 1$ hold during $i < df_0[1] - 1$.

³ The case of $df_0[1] = 254$ is omitted since i indicates the second nonzero bit difference $df_0[2] = 255$.

Fig. 8. Experimental results and ϵ of Event[3]

Fig. 9. Prob $[\Delta Z = 0]$ ($df_0[2] = 255$)

Fig. 10. Comparison of Prob [Event[3]] and Prob $[\Delta Z = 0]$

Outputs before the nonzero-bit difference:

Let us discuss $\text{Prob}[\Delta Z = 0]$ in $r = \text{df}_0[1]$, where there exists originally⁴ a nonzero-bit difference. $\text{Prob}[\Delta Z = 0]$ is estimated theoretically in Theorem 5. From the fact that the percentage absolute error $\epsilon < 1$ holds in $2 \leq \forall \text{df}_0[1] \leq 254$, we see that our theoretical formulae closely match the experimental results in any Diff_0 .

Let us discuss the relation between two events of $\Delta Z = 0$ and $\text{Event}[3]$ in $r = \text{df}_0[1]$. Figures 8 and 9 show that $\text{df}_0[1]$ satisfying $\text{Prob}[\Delta Z = 0] > 30\%$ is almost the same as $\text{df}_0[1]$ satisfying $\text{Prob}[\text{Event}[3]] > 30\%$. In fact, $P_1 = \text{Prob}[\Delta Z = 0]$ in the round $\text{df}_0[1]$ deeply affects $P_2 = \text{Prob}[\text{Event}[3]]$ as we have seen in Theorem 5. Figure 10 shows the comparison between P_1 and P_2 for $2 \leq \text{df}_0[1] \leq 255$, where two percentage absolute errors are listed, $\epsilon_1 = \frac{|P_2 - P_1|}{P_2}$ and $\epsilon_2 = \frac{|P_2 - (\text{theoretical})\text{Prob}[\text{Event}[3]]|}{P_2}$ for experimental values P_1 and P_2 . The horizontal axis represents $\text{df}_0[1] = 2, \dots, 254$. The left side of vertical axis represents $\text{Prob}[\Delta Z = 0]$, and the right side represents the percentage absolute error. Experimental results show that $\epsilon_1 < 5$ (resp. 10) if $\text{df}_0[1] > 15$ (resp. $\text{df}_0[1] > 9$) and, thus, we see that the observable event $\Delta Z = 0$ can indicate that the internal event $\text{Event}[3]$ occurs with extremely high probability.

Figure 11 shows experimental results of $\text{Prob}[\Delta Z = 0]$ in the round $\text{df}_0[1] = 3$ in each case of $4 \leq \text{df}_0[2] \leq 255$ ($\text{df}_0[1] = 3$), and percentage absolute error. The horizontal axis represents $\text{df}_0[2]$. The left side of vertical axis represents $\text{Prob}[\Delta Z = 0]$, and the right side represents the percentage absolute error. The percentage absolute error $\epsilon < 0.8$ holds in $4 \leq \forall \text{df}_0[2] \leq 255$. We see that our theoretical formulae closely match the experimental results independent of another nonzero-bit difference $\text{df}_0[2]$.

5.3 Experimental Results of biases in $S_0[1]$ and $S_0[2]$

Let us discuss $\text{Event}[3]$ when $\text{df}_0[1] = 3$ in detail, where the error $\epsilon > 10$ (Table 1). Theorem 3 says that both $S_0[1]$ and $S_0[2]$ determine $\text{Event}[3]$, that is, $\text{Event}[3] \iff [S_0[1] = 3] \vee [S_0[1] \neq 2, 3 \wedge S_0[1] + S_0[2] = 3]$. Here we investigate the bias in $S_0[1]$ and $S_0[2]$ from the point of view of $\text{Event}[3]$.

Figure 12 shows experimental results concerning the occurrence of $S_0[1]$ with $0 \leq S_0[1] \leq 255$, and the percentage absolute error, where the theoretical value (a random association) of occurrence of each $S_0[1]$ is $\frac{1}{N} = 3.906 \times 10^{-3}$. Figure 13 shows experimental results concerning the occurrence of $S_0[2]$ when $S_0[1] = 3$, and the percentage absolute error, where the theoretical value (a random association) of occurrence of each $(S_0[1] = 3, S_0[2])$ is $\frac{1}{N(N-1)} = 1.532 \times 10^{-5}$. The horizontal axis represents $S_0[1]$ or $S_0[2]$. The left side of vertical axis represents each probability, and the right side represents each percentage absolute error.

These experimental results indicate a non-uniform distribution of $S_0[1]$ and $S_0[2]$ when $S_0[1] = 3$. Tables 2 and 3 show some cases that indicate a non-uniform

⁴ If $\text{Event}[3]$ has occurred in the round $r < \text{df}_0[1]$, then $\text{df}_0[1]$ is not an index of nonzero bit difference.

distribution as follows:

$$\begin{aligned} \text{Prob}[S_0[1] = 3] &= 5.303 \times 10^{-3} > 3.906 \times 10^{-3}, \\ \text{Prob}[S_0[1] = 3 \wedge S_0[2] = x] &> 2.0 \times 10^{-5} > 1.532 \times 10^{-5} \text{ for } \forall x \leq 135, \\ \text{Prob}[S_0[1] = 3 \wedge 0 \leq S_0[2] \leq 128] &= 3.05299 \times 10^{-3} > 1.9531 \times 10^{-3}. \end{aligned}$$

These non-uniform distribution will be used for a new cryptanalytic analysis in Section 6.

6 A new cryptanalytic analysis

Here we investigate how to analyze the internal state of S or j . Assume that two permutations S and S' with $\text{Diff}_0 = \{\text{df}_0[1], \text{df}_0[2]\}$ in the initial round are given, and that both outputs of PRGA are observable.

Then, by observing both outputs Z and Z' of PRGA, we can recognize the index of the first nonzero-bit difference from the first round in which both outputs are not equal. This is investigated in Section 5.2. Therefore, if neither $\text{df}_0[1]$ nor $\text{df}_0[2]$ are known, the first nonzero-bit difference is predictable.

Consider the case of $\text{df}_0[1] = 2$. By checking whether $\Delta Z = 0$ in the 2nd round, we can recognize whether **Event[3]** has occurred. If **Event[3]** has occurred, then $S_0[1] = 2$ holds from Theorem 3. The experimental result shows $\text{Prob}[\text{Event[3]} \mid \text{df}_0[1] = 2] = 0.005350$ (see Table 1). However, if we try to predict $S_0[1]$ from a random association, then the probability is $1/256 = 0.003906$. Therefore, one can guess $S_0[1]$ with an additional advantage of $\frac{0.005350 - 0.003906}{0.003906} \times 100 = 36.9\%$.

Consider the case of $\text{df}_0[1] = 3$. By checking whether $\Delta Z = 0$ in the 3rd round, we can recognize whether **Event[3]** has occurred. Let us discuss how to predict both $S_0[1]$ and $S_0[2]$. If **Event[3]** has occurred, then $[S_0[1] = 3] \vee [S_0[1] \neq$

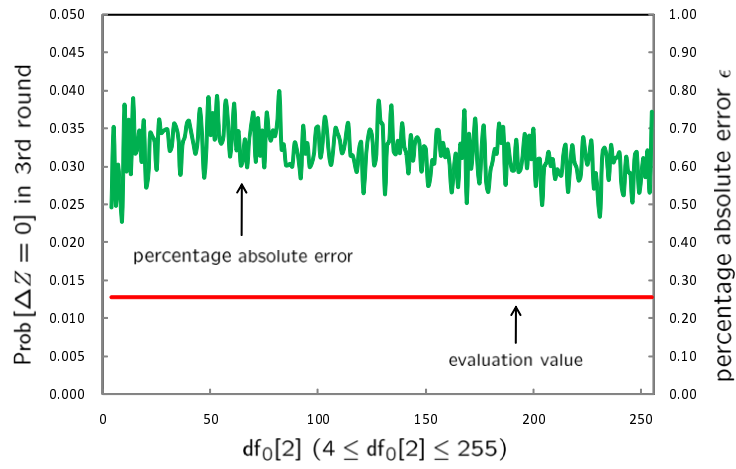

Fig. 11. Prob $[\Delta Z = 0]$ ($df_0[1] = 3$)

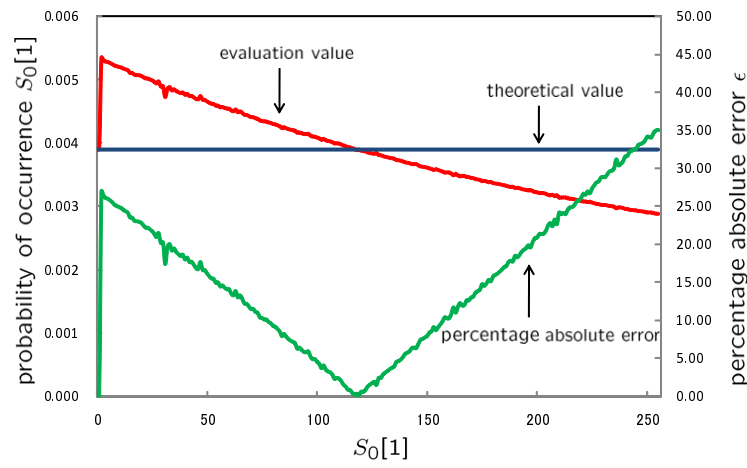

Fig. 12. Occurrence of $S_0[1]$

Fig. 13. Occurrence of $S_0[2]$ when $S_0[1] = 3$

$2, 3 \wedge S_0[1] + S_0[2] = 3]$ holds, from Theorem 3. In the case of $S_0[1] = 3$, the experimental results show that $\text{Prob}[\text{Event}[3] \mid \text{df}_0[1] = 3] = 0.009069$ (see Table 1) and $\text{Prob}[S_0[1] = 3] = 0.0053$ (see Table 2). On the other hand, we predict $S_0[2]$ with the probability $1/255$. Therefore, we can predict $(S_0[1], S_0[2])$ with the probability $0.0053 \times 1/255 = 2.078431 \times 10^{-5}$. In the case of $[S_0[1] \neq 2, 3 \wedge S_0[1] + S_0[2] = 3]$, if $S_0[1]$ is predicted, then $S_0[2]$ can be predicted promptly. We find that $\text{Prob}[\text{Event}[3] \wedge [S_0[1] \neq 2, 3] \wedge [S_0[1] + S_0[2] = 3]] = (0.009069 - 0.0053) \times 1/254 = 1.483858 \times 10^{-5}$. Therefore, we can predict $(S_0[1], S_0[2])$ with the probability 1.483858×10^{-5} . Taking both together, the probability to predict $(S_0[1], S_0[2])$ is $2.078431 \times 10^{-5} + 1.483858 \times 10^{-5} = 3.562289 \times 10^{-5}$. On the other hand, if we try to predict $(S_0[1], S_0[2])$ from a random association, then the probability is $1/256 \times 1/255 = 1.531863 \times 10^{-5}$. Therefore, one can guess $(S_0[1], S_0[2])$ with an additional advantage of $\frac{3.562289 - 1.531863}{1.531863} \times 100 = 132.54\%$.

7 Conclusion

In this paper, we have investigated, for the first time, correlations between two permutations, S and S' , with some differences in the initial round. We have shown that correlations between two permutations S and S' remain before “ i ” is in the position where the nonzero-bit difference exists in the initial round, and that the correlations remain with non negligible probability even after “ i ” passed by the position. All theoretical results have been confirmed experimentally.

Our results imply that the same correlations between two permutations will be observed with non negligible probability after the 255-th round. This reveals a new inherent weakness of shuffle-exchange-type PRGA. We have also investigated how to predict inner states such as S and j and shown that we can guess inner states with an additional advantage.
